EMPIRICAL MODELING OF THE THERMOSPHERE: AN OVERVIEW

A. Hedin, NASA/Goddard Space Flight Center

Hedin gave a summary of thermospheric density modeling history and standard atmospheres. In particular, he compared and contrasted the approaches of the Jacchia and MSIS models. His conclusions were that the Jacchia models are best if drag is the primary concern. MSIS is superior for variations in composition and temperature variations and comparison with theoretical models is facilitated by the use of spherical harmonics, which also provide a simple and consistent way of obtaining simplifications.

## ADVANTAGES/DISADVANTAGES

## 1. Jacchia

- a. Theoretically best if drag is primary quantity desired without high resolution and for satellite geometries and orbits similar to those used in generating the model. However, drag coefficients used in density derivation need to be more carefully specified if original drag is to be reproduced. Inaccurate specification of composition (e.g. He bulge) may result in inaccurate drag.
- b. Absolute total density dependent on the drag coefficient rather than the instrument calibration. However, dependence of drag coefficients on composition and extreme geometries may be a problem. Model predictions of composition and temperature are derived from auxiliary data or assumptions and may not be realistic.
- c. Formulation has particular difficulty coping with minor constituent variations found by mass spectrometers and cumbersome pseudotemperatures of J77 help only a little.

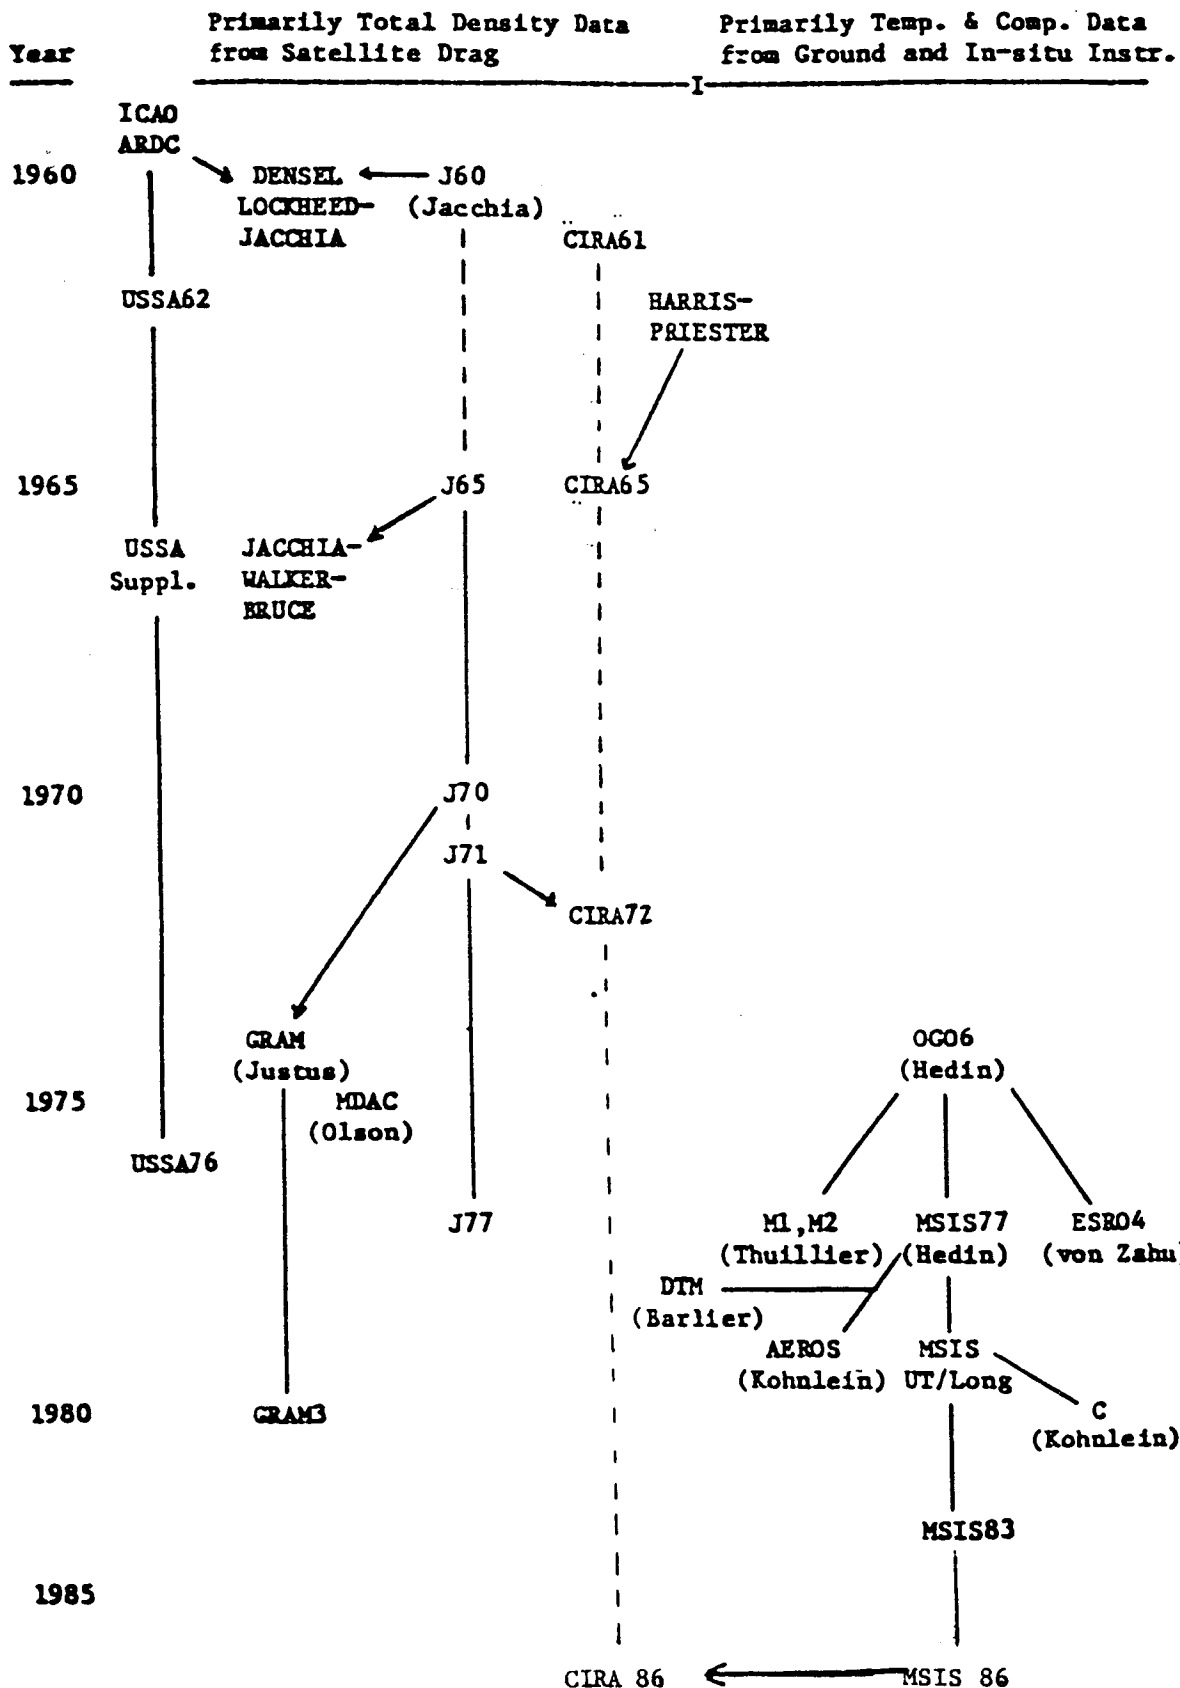

## 2. MSIS

- a. Best for composition/temperature variations, but agrees with drag models in overall averages.
- b. Provides better resolution of variations (including total density) in local time, etc.

PRECEDING PAGE BLANK NOT FILMED

- c. Absolute densities dependent on individual calibration constants for contributing instruments but model accuracy should be better than that of an individual instrument.
- d. Spherical harmonics facilitate systematic increase in model resolution and comparison with theoretical models. Similarly, complexity can be reduced if desired by dropping higher harmonics or unneeded effects.
- e. No numerical integration for faster execution speed.

# Historical Development of Empirical Thermosphere Models

## MODEL DEVELOPMENT

### A. Jacchia

#### 1. J65

- a. Earliest comprehensive model based on drag. Lower boundary at 120 km.
- b. Static height profiles as function of exospheric temperature assuming hydrostatic/diffusive equilibrium.
- c. First to include four principal effects (diurnal/seasonal, semiannual, solar activity, magnetic activity) using ad hoc formulas for exospheric temperature to fill gaps.
- d. Introduced Bates type temperature profile (which can be integrated explicitly).

#### 2. J70 & J71

- a. Lower boundary at 90 km and more complicated temperature profile requiring numerical integration.
- b. Refinements and expansions of ad hoc formulas.
- c. Included factor of three winter helium bulge.
- d. J71 raised atomic oxygen at 150 km over J70.

#### 3. J77

- a. Inclusion of some results from mass spectrometers.
- b. Magnetic coordinates for magnetic activity effects.
- c. Composition phase through pseudo-temperatures.

### B. OGO-6/MSIS

#### 1. OGO-6 (1974)

- a. Earliest comprehensive model based on mass spectrometer data.
- b. Bates temperature profile above 120 km.
- c. Spherical harmonics for geographical/local time coordinates.
- d. Variable boundary at 120 km for He and O to represent phase differences between constituents. Height profiles assuming hydrostatic/diffusive equilibrium.
- e. Temperature inferred from N2 agreed well with incoherent scatter.

#### 2. MSIS 77

- a. Same format as OGO-6.
- b. Used mass spectrometer density data from five satellites and temperatures from four incoherent scatter stations.
- c. Variable boundary also for N2 so temperature depends on incoherent scatter and N2 scale heights.

#### 3. MSIS 79

- a. Introduced UT/Longitude variations for quiet and magnetic active times (alternative to magnetic coordinates). Temperature maximum and He minimum near magnetic pole.

#### 4. MSIS 83

- a. Density and temperature data from mass spectrometers on seven satellites, from five IS stations, and from rockets.
- b. Extended profiles below 120 km to 85 km using analytically integrable temperature profiles.
- c. Includes major variations in temperature and density below 120 km.
- d. Improved resolution in prediction of magnetic activity variations using time history of 3hr indices.

Fig. 13

Latitudinal variation of  $n(\text{He})$  at 1000 km altitude. The left part corresponds to  $F = \bar{F} = 150 \times 10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$  and  $K_p = 2$ . The right part corresponds to  $F = \bar{F} = 92 \times 10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$  and  $K_p = 2$ . Comparison with Jacchia 1971 and MSIS models. Barlier (1979)

EXOSPHERIC TEMPERATURE DISTRIBUTION AT NORTHERN SUMMER SOLSTICE  
 Jacchia J71 Model

Figure 8. Exospheric isotherms ( $^{\circ}\text{K}$ ) above the globe, computed from equations (15) and (16), for the case when the minimum temperature is  $1000^{\circ}\text{K}$ . Aitoff's equal-area projection; meridians of local solar time and parallels of latitude are drawn  $30^{\circ}$  apart. Top, equinox; bottom, northern summer solstice.
